

Accommodation of the eye to a close object	• Ciliary muscles contract • Suspensory ligaments relax • Lens is short and thick
Accommodation of the eye to a distant object	• Ciliary muscles relax • Suspensory ligaments pulled tight • Lens is long and thin
bright light	• Radial muscles of iris relax • Circular muscles of iris contracted • Contracted pupils (less light enters eye)
choroid	vascular membrane of the eyeball between the sclera and the retina & stops light reflecting around in the eye
ciliary body (muscle)	contracts and relaxes to change the shape of lens
Cones	retinal receptor cells that are concentrated near the center of the retina and that function in daylight or in well-lit conditions. The cones detect fine detail and give rise to color sensations.
cornea	transparent front part of the eye that refracts light
dim light	• Radial muscles of iris contracted • Circular muscles of iris relaxed • Dilated pupils (more light enters the eye)
fovea (Yellow Spot)	part of the retina with a high density of cones for the very sharp vision
iris	coloured muscular part of the eye that eye controls the pupils size

lens	transparent part of the eye that bends light (refracts)
optic disk (blind spot)	area on retina that is insensitive to light
optic nerve	where electrical impulses from retina travel to brain
pupil	opening in the iris that lets light through to the retina
retina	light sensitive membrane that converts light to electrical signals to the brain
Rods	retinal receptors that detect black, white, and gray; necessary for peripheral and twilight vision, when cones don't respond
sclera	dense white covering of the eye
suspensory ligament	ligament that controls the shape of the lens
vitreous humor	jellylike substance found behind the lens in the posterior cavity of the eye that maintains its shape
